

Carbon Capture and Storage (CCS) is essential for reducing carbon dioxide (CO2) emissions from industrial activities. Within the last decade, carbon emissions have seen a large increase in Texas due to the growing demand for energy driven by population growth. While the sedimentary basins in Texas have large potential for CCS, detailed site screening, ranking, and characterization are necessary to identify the most favorable geologic units within each basin for secure, long-term storage of CO2. This project aims to determine the CCS potential of the Fort Worth Basin in North Central Texas. This study first utilizes a modified method of basin screening and ranking for CCS to assess the different geologic units and five areas of the Fort Worth Basin. The ranking considers regional and local geologic and economic factors. The geologic units include the Cambrian and Ordovician dominated by limestone, Mississippian dominated by shale, and Pennsylvanian and lowermost Permian characterized by interbedded shale, sandstone, and limestone. These five areas, including the northeastern, eastern, southern, western and Bend Arch regions, are divided based on the Paleozoic tectonic and subsidence history. Our results show that the Pennsylvanian and lowermost Permian units in the northeastern, eastern, and Bend Arch areas have the highest suitability, and the Cambrian and Ordovician unit throughout the basin have the lowest suitability. The CCS potential of the Pennsylvanian and lowermost Permian in the northeastern part of the basin and the Bend Arch area will be examined in depth to quantitatively estimate the CCS potential.

Use site screening and ranking methods for various geological and economic factors to determine what sections and units of the Fort Worth Basin hold the highest potential for carbon capture and storage geared for use by major power generation stations.

# Site Charcterization for Potential Geologic Carbon Capture and Storage in the Fort Worth Basin, Texas
